Abstract

Clear-cutting of forests have pronounced effects on chemistry of soils and runoff water. The major effects are increased water yield, changes in nutrient cycles and increased leakage of the nutrients nitrate and potassium in runoff. As part of the national monitoring programme for long-range transported air pollutants, administered by the Norwegian Pollution Control Authority (SFT), four groundwater aquifers in southern Norway were monitored for acidification trends during the period 1980-1995. For the monitoring station, Langvasslia in southeastern Norway, sampling was continued until the end of 1999. This groundwater aquifer is located about 3 km north-east of the calibrated catchment Lake Langtjern. The catchment of the groundwater aquifer, covered completely by Norway spruce, was totally clear-cut in September 1986 and was treated with glyphosate in summer 1991. The effects on the groundwater are generally similar to those observed in stream-water from clear-cut areas: increases in water runoff, water temperature, concentrations of K, NO₃ and organic carbon (TOC) and decrease in SO₄-concentration. In the groundwater aquifer also inorganic aluminum decreased and ANC increased more than would have been expected without clear-cutting. NO₃ concentrations are now almost back to the levels prior to clear-cutting, whereas K still shows elevated concentrations.

Preface

As part of the national monitoring programme for long-range transported air pollutants, administered by the Norwegian Pollution Control Authority (SFT), four groundwater aquifers in southern Norway were monitored for acidification trends during the period 1980-1995. Three of them, Birkenes, Åmli and Evje (from 1982) are located in Aust Agder county, whereas the fourth aquifer, Langvasslia, is located in Buskerud county. For economic reasons groundwater monitoring was officially terminated in 1995. The Norwegian Institute for Water Research (NIVA) and the Geological Survey of Norway (NGU) jointly sponsored the groundwater monitoring for 1996, hoping that the official monitoring could again be resumed by SFT. Unfortunately, this did not happen. Because the catchment of the groundwater aquifer in Langvasslia (LAG01) was clearcut in 1986, and that the effect on the water quality was still significant in 1996, sampling was continued by NIVA in order to follow the effects of clearcutting for some more years. The sampling was terminated at the end of 1999, thus giving a sampling period of 20 years. We present here trends and changes in water chemistry recorded for this particular groundwater aquifer with special emphasis on the effect of the clearcutting on groundwater chemistry. This report is based on a paper submitted to Hydrol. Earth System Sci.

Summary

Clear-cutting of forests have pronounced effects on chemistry of soils and runoff water. The major effects are increased water yield, changes in nutrient cycles and increased leakage of the nutrients nitrate and potassium in runoff. As part of the national monitoring programme for long-range transported air pollutants, administered by the Norwegian Pollution Control Authority (SFT), four groundwater aquifers in southern Norway were monitored for acidification trends during the period 1980-1995. For the monitoring station, Langvasslia in south-eastern Norway, sampling was continued until the end of 1999. This groundwater aquifer is located about 3 km north-east of the calibrated catchment Lake Langtjern. The catchment of the groundwater aquifer, covered completely by Norway spruce, was totally clear-cut in September 1986 and was treated with glyphosate in summer 1991. The effects the groundwater are generally similar to those observed in stream-water from clear-cut areas: increases in water runoff, water temperature, concentrations of K, NO₃ and organic carbon (TOC) and decrease in SO₄-concentration. In the groundwater aquifer also inorganic aluminum decreased and ANC increased more than would have been expected without clear-cutting. NO₃ concentrations are now almost back to the levels prior to clear-cutting, whereas K still show elevated concentrations.

1. Introduction

Clear-cutting of forests in lake catchments have pronounced effects on stream and lake water chemistry. Likens et al. (1970) reported on effects of clear-cutting and herbicide treatment in the hardwood forested Hubbard Brook watershed in New Hampshire, U.S.A. Large increases in streamwater concentrations for most major ions, especially nitrate and potassium, were recorded. Also, water yield increased substantially. Similar results were found from clear-cutting hardwood forests in the White Mountains of New Hampshire (Martin et al. 1985). Hornbeck et al. (1987) have extensively reported on effects of clear-cutting practices on runoff water in the Hubbard Brook watershed. The effect was at maximum one year after block cut harvest, giving about 100 % higher sum of measured ions than before harvest. By year 5 after harvest the sum of ions had returned to levels found before harvest. The large increase in nitrate was largely balanced by increases in calcium, magnesium and potassium. Potassium was the only ion that continued to increase at year 5 after the harvest period. Neal et al. (1992a, 1992b) studied the effects of harvesting on stream water chemistry at an acidic and acid sensitive spruce forested area in mid-Wales. The effects of a 3-year conifer harvesting program showed that nitrate and potassium, initially almost quadrupled, remained high for 4 years. Concentrations of aluminum in soils and stream increased and stream pH and alkalinity declined for the first two years, after which the trends reversed to give conditions similar to those pertaining prior to felling. Rosén et al (1996) studied the runoff from 3 forested catchments during a 12-year period. Fifty percent and 95% of the surface of two of the areas were clear-cut, the third area was kept as a control. Average runoff increased by 85% and 110%, respectively, in the clear-cut areas. Stream chemistry changes were identified mainly on increased concentrations of potassium, ammonium, nitrate, organic- and total nitrogen. At the end of the 8-year study period the run-off and stream water successively returned to pre-cut conditions.

As part of the national monitoring programme for long-range transported air pollutants, administered by the Norwegian Pollution Control Authority (SFT) (Johannessen 1995), four groundwater aquifers in southern Norway were monitored for acidification trends during the period 1980-1995. For economic reasons groundwater monitoring was officially terminated in 1996. For one of the monitored stations, Langvasslia (station code LAG01) in South Eastern Norway, sampling was continued by NIVA as a research project until the end of 1999.

The groundwater aquifer at Langvasslia is located about 3 km north-east of the calibrated catchment lake Langtjern (Henriksen and Wright 1977, Skjelkvåle and Henriksen 1995) (Figure 1) The catchment of the groundwater aquifer, covered completely by Norway spruce, was totally clear-cut without warning by the landowner in September 1986. The slash was not burned or removed. The catchment was treated further with glyphosate in summer 1991 to stop growth of deciduous trees. As a consequence of these manipulations, the water quality of the groundwater aquifer changed considerably. This offered the opportunity to study the effects of clear-cut on shallow groundwater aquifer with a small catchment. We present here trends and changes in water chemistry recorded for the groundwater aquifer at Langvasslia and with special emphasis on the effect of the clear-cutting on groundwater chemistry.

Figure 1. Location of the Langvasslia groundwater aquifer relative to the calibrated catchment Lake Langtjern.

Figure 2. A picture of the catchment of the groundwater aquifer in 1999. The new 13-year-old forest is seen in the foreground. The dense old forest in the background is similar to the forest before clear-cutting.

2. Site description

The bedrock in the area consists of banded granodioritic gneiss with layers of amphibolites of Precambrian age (Smithson 1963), overlain by till. The groundwater aquifer unconfined and located in till deposits on a hill slope. The monitoring screen well was placed in the discharge area of the aquifer, near the bottom of the hill slope at an altitude of 425 m.a.s. The monitoring screen well is located in a basal till overlying the bedrock. The thickness of the till is about 1 - 3 m, with many blocks. The till is probably affected by frost, and thus has become more permeable than a typical basal till.

3. Sampling and analysis.

The monitoring 5/4" screen well was placed just above a spring outlet, with the groundwater intake for chemical analysis from 0.75 - 1.75 m (1 m filter) below the surface. Groundwater samples were collected after 15 minutes pumping time. Groundwater level and groundwater temperature were measured weekly. Groundwater samples were collected monthly when possible and water yield was measured at the same time. Groundwater sampling was started in May 1980, all samples were analyzed at the Norwegian Institute for Water Research using standardized methods for the following variables: pH, Conductivity, Ca, Mg, Na, K, Cl, SO₄, NO₃, alkalinity, reactive Al, non-labile Al, SiO₂, turbidity and permanganate value.

4. Results and discussion

4.1 Precipitation chemistry and amounts

As part of the national monitoring programme for long-range transported air pollutants precipitation chemistry and precipitation amounts were determined by bulk sampling on a daily basis for the period 1974 to 1992 and on a weekly basis thereafter (Tørseth *et al.* 1999). (Figure 3). The precipitation station was located at Sønsteby farm at Gulsvik 7 km west of groundwater aquifer.

Figure 3. Yearly weighted average concentrations in wet deposition and yearly precipitation amounts at monitoring station Gulsvik in Buskerud county, Norway, located 7 km west of groundwater aquifer (Tørseth et al. 1999).

The trends in deposition at Gulsvik follow the general patterns for southern Norway: a significant downward trend in sulphur deposition from the early 1980's and, as a consequence, a marked increase in pH, but no significant changes in N-deposition until the last three years. (Tørseth *et al.* 1999). In 1979 the concentrations of S, N and H^+ were the highest ever measured at Gulsvik. The precipitation amounts were significantly above the average for the measurement period during the later 1980's, thereafter precipitation amounts returned to near the average for the measurement period. During the last three years, however, the amount of precipitation has again increased.

4.2 Groundwater level, temperature and yield

The groundwater level generally varies with season (figure 4): lower levels in late winter and late summer and higher water levels in spring after snowmelt and in late fall due to increased precipitation amounts. The groundwater aquifer is shallow and therefore sensitive to variations in precipitation amounts. The records include several dry periods (Figure 4). These occur all during dry summers, such as in September 1981, July 1983, July 1986, and in August-September 1991 and 1995. Water temperature varies between nearly 0° C during winter and up to 10° C during the summers of 1988 and 1997. 89% of the temperature observations above 7°C were measured in summer months <u>after</u> clear-cutting. There is further a tendency to higher water levels for two years after clear-cutting (Figures 4)

and 6a), but this can partly be caused by higher precipitation amounts for those two years (Figure 3). The clear-cut also resulted in higher summer temperatures in the groundwater (Figure 5).

The water yield of the groundwater aquifer was measured only when a water sample was taken, normally once a month. The water yield measurements were stopped in December 1998. During the sampling period 126 water yield measurements were taken compared with 895 water level measurements. As is expected there is a clear relationship between water level and water yield (Figure 6b).

Figure 6. Variations in water yield during the measurement period (a), and relationship between water level and water yield (b).

5. Water chemistry

Water samples for chemical analyses were collected once a month whenever possible. Due to occasionally frozen well or very low groundwater level, the measurement frequency was for most years less than once a month. These irregularities are reflected in the number of samples collected per year (Table I). The yearly average values for the measured chemical variables of the groundwater aquifer for the measurement period 1980-1999 (Table I) show that the groundwater is acidic, has high concentrations of labile inorganic aluminum (L-Al) and has low base cation concentrations. The groundwater is highly influenced by soil water, as indicated by the high content of organic matter (TOC). Because of its location inland Norway the groundwater is little influenced by sea salt spray, as reflected in the low concentrations of chloride and sodium. The average ratio of Na/Cl is 1.44 as compared to the seawater ratio of 0.85, indicates the presence of some geologic sources of sodium in the catchment of the aquifer.

Table I. Yearly average values for analyzed variables in the groundwater aquifer Langvasslia in Buskerud county, Norway. Total organic carbon (TOC) have been estimated from measured permanganate values (PERM) by the empirical equation: TOC = PERM/1.24 based on 87 samples of surface waters in Norway (not published). R-Al = Reactive Al, Org-Al = non-labile Al, L-Al = Labile Al. N= Number of samples per year.

6. Comparison with surface water

The monitoring of the groundwater aquifer was designed for studying the long-term effects of acid rain on groundwater chemistry. Since the clear-cutting of its catchment came as a surprise, no reference groundwater aquifer was established. However, one of the inlets to lake Langtjern (station code LAE03, see Figure 1) is located in similar geologic settings as the groundwater aquifer and located only 3.5 km away. Here, weekly samples have been collected since 1973 (Skjelkvåle and Henriksen 1995). We have compared the yearly average values for the period 1980-1985 (prior to clear-cut) for both sites (Table II). The concentrations of major constituents are very similar. Marked differences in concentrations are found in $H^+(pH)$, TOC and aluminum species. Groundwater has normally significantly higher CO₂-pressure than surface water. Norton and Henriksen (1983) found for the particular aquifer studied here that the pCO₂ at the time of sampling was $10^{-2.08}$ at pH 5.14. After purging the sample with N₂ the pCO₂ rose to $10^{-3.33}$ and the pH rose to 5.49.

A major difference is found for labile inorganic aluminum, the species considered being toxic to fish. The concentration in groundwater is 7 times higher than in surface water (Table II). The groundwater has percolated through the unsaturated zone, and thus its water chemistry reflects the net integrated effects of the processes taking place in this zone. Norton and Henriksen (1983) suggest that aluminum may be transported by dissociation of H_2CO_3 . Since the groundwater aquifer is highly over saturated with CO_2 , the dissociation of H_2CO_3 produces concentrations of H^+ capable of rendering particulate Al soluble, and the HCO_3^- formed may serve as a mobile anion and facilitate the transport of the Al.

Table II. Yearly average chemistry for an inlet creek to lake Langtjern (LAE03) and Langvasslia groundwater aquifer (LAG01) prior to clear-cut (1980-1985).

	рН	Са	Mg	Na	к	CI	SO4	NO₃	ANC	тос	R-AI	Org-Al	L-AI
		mg l ⁻¹	mg l ⁻¹	mg l⁻¹	mg l⁻¹	mg l ⁻¹	mg l⁻¹	µg l⁻¹	µeq l ⁻¹	mg C I ⁻¹	μg ^{I-1}	µg ^{⊦1}	μg ^{Ι-1}
Groundwater	5.16	1.14	0.23	1.17	0.07	0.7	4.7	7	8	7.8	222	122	186
Surface water	4.68	1.11	0.24	0.61	0.09	0.8	3.6	16	5	13.7	92	76	26

Figure 7 shows variations in several chemical variables during the period 1980-1999 based on the individual observations for Langvasslia groundwater aquifer. In order to assess the effect of the clearcut on water chemistry, we have also plotted the yearly average values for both the aquifer and the inlet stream to Langtjern (see Table II) for most of the variables (Figure 8). Below we discuss the effect of clear-cutting as superimposed on the general trends in the surface water.

6.1 Nitrate and potassium

The most marked effect of the clear-cutting is the sharp increase in the concentrations of nitrate (NO₃) and potassium (K) (Figure 7, upper panel) due to less nutrient uptake in the catchment and increased mineralization of organic matter such as dead roots. Before the clear-cutting nitrate and potassium concentrations were low, potassium about 0.08 mg/l and nitrate less than 10 μ gN/l. After clear-cutting potassium increased almost immediately while nitrate started to increase a year later. Nitrate decreased during growing season every year and increased during the dormant season. The addition of glyphosate in 1991 led to increased leaching of both nitrate and potassium, especially high nitrate peaks were observed during the dormant season until 1995.

Figure 7. Langvasslia groundwater aquifer: Variations in several chemical variables during the period 1980-1999 based on individual observations.

Figure 8. Yearly average values for several components in Langvasslia groundwater aquifer (groundwater) with corresponding values for the inlet stream to Langtjern (surface water) for the period 1980-1999. ANC = acid neutralizing capacity, $ECM^* = non-marine Ca+Mg$. $ESO4^* = non-marine SO_4$.

In 1997 the concentration levels of nitrate and potassium were back to the levels before the glyphosate treatment, but still significantly higher than before the clear-cutting. During the last two years, however, the nitrate concentrations were also low during the dormant season and should reach the levels before clear-cut in the near future. Potassium concentrations are still high and appear to have stabilized at a higher level than before clear-cut.

These general trends in leaching of nitrate and potassium are in general agreement with the observations made in other clear-cut in the U.S, UK and Sweden (Likens *et al.* 1970, Neal *et al.* 1992a, 1992b, and Rosén et al 1996). At Langvasslia by 1999, 13 years after clear-cut, nitrate is almost back to the concentrations before the clear-cut. This time span is substantially longer than those reported from other clear-cut experiments. Both Hornbeck *et al.* (1987) and Neal *et al.* (1992b) reported about 5 years before nitrate returned to pre harvest conditions. Rosén *et al.* (1996) found that at the end of the 8 year study period the run-off and stream water successively returned to pre-cut conditions. The extended recovery time for the Langvasslia aquifer could be caused by the glyphosate treatment 5 years after the clear-cut, because the deciduous vegetation growth was stopped to allow the coniferous trees the possibility to dominate, as they do today.

6.2 Sulphate

Fuller *et al.* (1987) showed that whole-tree harvesting in Hubbard Brook Experimental Forest lead to increased mineralization and nitrification and consequently to substantial NO₃ loss, acidification of soil solutions and increased soil adsorption of SO₄. As a consequence, stream-water concentrations and effluxes of SO₄ declined and NO₃ increased after tree harvesting. At the Langvasslia aquifer sulphate concentrations were substantially higher than in the surface water before clear-cut (Figure 8), but started as for the surface water to decline before the clear-cut. After the clear-cut, however, the groundwater concentrations of SO₄ declined at a faster rate than surface water. This reduction in concentration can largely be explained by reduced scavenging of gaseous and particulate sulphur species due to the removal of the trees. One year after clear-cut the concentrations both in groundwater and in surface water are similar, and the concentrations remained fairly constant until 1993 when the groundwater concentrations again were higher than the surface water concentrations. Apparently, the growing forest again scavenged significant amounts of sulphur from the atmosphere. Thus there is no need to invoke changes in soil acidity and SO₄ adsorption to explain the observed pattern in SO₄ concentrations in groundwater at Langvasslia.

6.3 ANC and base cations (Ca+Mg)

A characteristic aspect of surface water quality recovery from acidification in Norway is the decline in sulphate concentration and a stable base cation concentration (Skjelkvåle *et al.* 1998). <u>A</u>cid <u>N</u>eutralizing <u>C</u>apacity (ANC) (Reuss and Johnson 1986) has increased in the surface water, especially since 1990 (Figure 8), due to the reduced sulphur deposition in Norway (Skjelkvåle *et al.* 1998). ANC in the groundwater has also increased, and follows largely the same pattern as for the surface water (see Figure 7 lower panel and Figure 8), but ANC has increased substantially more than in the surface water since the early 1990's.

The ANC of the groundwater aquifer increased significantly after clear-cutting in spite of rather stable sulphate concentrations. This is because the concentrations of non-marine base cations increased during the same period in contrast to the surface water (Figures 7 and 8). After 5 years, however, base

cation concentrations started to decline approaching the levels of the surface water. The "episodic" base cation increase can indicate a short-lived change in weathering or mineralization of organic matter in the soil due to the clear-cut.

6.4 Total organic carbon and labile aluminum

Total organic carbon increased significantly after clear-cutting (Figure 7 center panel, Figure 8), but declined again after a few years. The high peaks of TOC all occur in the summer (Figure 8), and the peaks are highest the first years after clear-cut. The TOC peaks decreased in the first part of 1990's, but have increased significantly during the later years. This is in accordance with the general increase in TOC of surface water observed in southern Norway (SFT 1999) as also reflected in the TOC trend in the inlet stream to Langtjern (Figure 8).

The concentrations of labile Al also increased sharply during the summer months after clear-cut (Figure 7 center panel), especially 2-3 years after clear-cut. Labile Al started to decline around 1990, following the general trends in surface waters in Norway (Skjelkvåle *et al.* 1998), as also reflected in the inlet stream to Langtjern (Figure 8).

7. Concluding remarks

Likens *et al.* (1970) suggest, based on the experience from Hubbard Brook, that clear-cutting reduces shading and evaporation, thus increasing temperature and water content of the forest floor. Decomposition of organic matter proceeds more rapidly, and nitrification increases greatly, leading to higher NO₃-leaching. Also potassium leaching increases due to reduced nutrient uptake by vegetation. These conclusions are in accordance with findings by other researchers (Vitousek *et al.* 1979, Rosén 1984, Martin *et al.* 1985, Hornbeck *et al.* 1987, Rosen *et al.* 1996, Neal *et al.* 1992a, 1992b). Martin *et al.* (1985), however, found from studies in clear-cut areas in New England, US.A that NO₃-leaching into streams was insignificant in most cases. He explained these differences as to be due to the characteristics of the catchments. Although the increased nitrification may cause high NO₃-concentrations in the soil solution, the NO₃ may not reach the stream body because of de-nitrification in the soil is important for the effect of clear-cutting on NO₃-content of soil water and thus also on groundwater. In the catchment of Langvasslia groundwater aquifer the soil cover is thin, and thus the retention time of the water in the soil profile is short. Consequently, de-nitrification reactions and uptake by vegetation are low, leading to high leaching of NO₃ into the groundwater.

The elevated leaching of NO_3 and K persisted for 11 years, and NO_3 is now almost back to the levels before the clear-cut. Other studies indicate shorter recovery time for nitrate. The extended recovery time for the Langvasslia aquifer could be caused by the glyphosate treatment 5 years after the clearcut, because the deciduous vegetation growth was stopped to give the coniferous trees the possibility to dominate. The leaching of K, however, is still higher than before clear-cut. A similar observation was made by Hornbeck *et al.* (1987) in a study of 10 years of recovery from clear-cutting in Hubbard Brook, where the effects of the cutting remained evident through the 10 year of re-growth.

Appendix B.

Acid Rain Research Reports

- 1/1982. Henriksen, A. 1982. Changes in base cation concentrations due to freshwater acidification.50 pp. Out of print.
- 2/1982. Henriksen, A. and Andersen, S. 1982. Forsuringssituasjonen i Oslomarkas vann. 45 pp. Out of print.
- 3/1982. Henriksen, A. 1982. Preacidification pH-values in Norwegian rivers and lakes. 24 pp. Out of print.
- 4/1983. Wright, R.F. 1983. Predicting acidification of North American lakes. 165 pp.
- 5/1983. Schoen, R., Wright, R.F. and Krieter, M.1983. Regional survey of freshwater acidification in West Germany (FRG). 15 pp.
- 6/1984. Wright, R.F. 1984. Changes in the chemistry of Lake Hovvatn, Norway, following liming and reacidification. 68 pp.
- 7/1985. Wright, R.F. 1985. RAIN project. Annual report for 1984. 39 pp.
- 8/1985. Lotse, E.and Otabbong, E.1985. Physiochemical properties of soils at Risdalsheia and Sogndal: RAIN project. 48 pp.
- 9/1986. Wright, R.F. and Gjessing, E. 1986. RAIN project. Annual reportfor 1985. 33 pp.
- 10/1986. Wright, R.F., Gjessing, E., Semb, A. and Sletaune, B. 1986. RAIN project. Data report 1983-85. 62 pp.
- 11/1986. Henriksen, A., Røgeberg, E.J.S., Andersen, S. and Veidel, A. 1986. MOBILLAB-NIVA, a complete station for monitoring water quality. 44 pp.
